**Binary Trees, Heaps**

A binary tree (δυαδικό δέντρο) is a set of nodes such that:
- Exactly one node is called the root
- All nodes except the root have exactly one parent
- Each node has at most two children
  - and the are ordered: called left and right

---

**Example: a binary tree**

```
R
 S  T
 X  Y  U  V
 Z  W
```

**Example: a different binary tree**

```
R
 S  T
 X  Y  U  V
 Z  W
```

Whether a child is left or right matters.
Terminology

- **path**: sequence of nodes traversing from parent to child (or vice-versa)
- **length** of a path: number of nodes - 1 (= number of "moves" it contains)
- **siblings**: children of the same parent
- **descendants**: nodes reached by travelling downwards along any path
- **ancestors**: nodes reached by travelling upwards towards the root
- **leaf/external node**: a node without children
- **internal node**: a node with children

Nodes tree can be arranged in **levels/depths**:
- The root is at **level 0**
- Its children are at **level 1**, their children are at **level 2**, etc.
- Note: node level = length of the (unique) path from the root to that node
- **height** of the tree: the largest depth of any node
- **subtree** rooted at a node: the tree consisting of that node and its descendants

Complete binary trees

A binary tree is called **complete** (πλήρες) if
- All levels except the last are "full" (have the maximum number of nodes)
- The nodes at the last level fill the level "from left to right"

Example: complete binary tree
**Example: not complete binary tree**

**Level order**
Ordering the nodes of a tree **level-by-level** (and left-to-right in each level).

**Nodes of a complete binary tree**
- How many nodes does a complete binary tree have at each level?
  - At most
    - 1 at level 0.
    - 2 at level 1.
    - 4 at level 2.
    - \(2^k\) at level \(k\).
Properties of binary trees

- The following hold:
  - $h + 1 \leq n \leq 2^{h+1} - 1$
  - $1 \leq n_E \leq 2^h$
  - $h \leq n_I \leq 2^h - 1$
  - $\log(n + 1) - 1 \leq h \leq n - 1$

- Where
  - $n$: number of all nodes
  - $n_I$: number of internal nodes
  - $n_E$: number of external nodes (leaves)
  - $h$: height

Properties of complete binary trees

$h \leq \log(n)$

- Very important property, the tree cannot be too "tall!"
- Why?
  - Any level $l < h$ contains exactly $2^l$ nodes
  - Level $h$ contains at least one node
  - So $1 + 2 + \ldots + 2^{h-1} + 1 = 2^h - 1 \leq n$
  - And take logarithms on both sides

How do we represent a binary tree?

Sequential representation

Store the entries in an array at level order.

- Common for complete trees
- A lot of space is wasted for non-complete trees
  - missing nodes will have empty slots in the array
How to find nodes

<table>
<thead>
<tr>
<th>To Find</th>
<th>Use</th>
<th>Provided</th>
</tr>
</thead>
<tbody>
<tr>
<td>The left child of $A[i]$</td>
<td>$A[2i]$</td>
<td>$2i \leq n$</td>
</tr>
<tr>
<td>The right child of $A[i]$</td>
<td>$A[2i+1]$</td>
<td>$2i+1 \leq n$</td>
</tr>
<tr>
<td>The parent of $A[i]$</td>
<td>$A[i/2]$</td>
<td>$i &gt; 1$</td>
</tr>
<tr>
<td>Whether $A[i]$ is a leaf</td>
<td></td>
<td>$2i &gt; n$</td>
</tr>
</tbody>
</table>

Heaps

A binary tree is called a heap (σωρός) if

- It is complete, and
- each node is greater or equal than its children

(Sometimes this is called a max-heap, we can similarly define a min-heap)

Example

Heaps and priority queues

- Heaps are a common data structure for implementing Priority Queues
- The following operations are needed
  - find max
  - insert
  - remove max
  - create with data
- We need to preserve the heap property in each operation!
Find max

- Trivial, the max is always at the root
  - remember: we always preserve the heap property
- Complexity?

Inserting a new element

- The new element can only be inserted at the end
  - because a heap must be a complete tree
- Now all nodes except the last satisfy the heap property
  - to restore it: apply the bubble_up algorithm on the last node

Inserting a new element

bubble_up(node)

- Before
  - node might be larger than its parent
  - all other nodes satisfy the heap property
- After
  - all nodes satisfy the heap property
- Algorithm
  - if node > parent
    - swap them and call bubble_up(parent)

Example insertion
**Example insertion**

- Inserting 15 and running bubble_up
- Inserting 12 and running bubble_up

**Complexity of insertion**

- We travel the tree from the last node to the root:
  - on each node: 1 step (constant time)
- So we need at most $O(h)$ steps:
  - $h$ is the height of the tree
  - but $h \leq \log n$ on a complete tree
- So $O(\log n)$
  - the “complete” property is crucial!

**Removing the max element**

- We want to remove the root:
  - but the heap must be a complete tree
- So swap the root with the last element:
  - then remove the last element
- Now all nodes except the root satisfy the heap property:
  - to restore it: apply the bubble_down algorithm on the root
Removing the max element

bubble_down(node)

- **Before**
  - node might be **smaller** than any of its children
  - all other nodes satisfy the heap property

- **After**
  - all nodes satisfy the heap property

- **Algorithm**
  - max_child = the largest child of node
  - If node < max_child
    - swap them and call bubble_down(max_child)

Example removal

Removing 9 and restoring the heap property

Complexity of removal

- We travel a single path from the root to a leaf
- So we need at most $O(h)$ steps
  - $h$ is the height of the tree
- Again $O(\log n)$
  - again, having a complete tree is crucial
Building a heap from initial data

- What if we want to create a heap that contains some initial values?
  - We call this operation heapify

- "Naive" implementation:
  - Create an empty heap and insert elements one by one

- What is the complexity of this implementation?
  - We do $n$ inserts
    - Each insert is $O(\log n)$ (because of bubble_up)
    - So $O(n \log n)$ total

- Worst-case example?
  - Sorted elements: each value with have to fully bubble_up to the root

Efficient heapify

- Better algorithm:
  - Visit all internal nodes in reverse level order
    - Last internal node: $\frac{n}{2}$ (parent of the last leaf $n$)
    - First internal node: 1 (root)
  - Call bubble_down on each visited node

- Why does this work?
  - When we visit node, its subtree is already a heap
    - Except from node itself (the precondition of bubble_down)
  - So bubble_down restores the heap property in the subtree
  - After processing the root, the whole tree is a heap

Heapify example

Visit internal nodes in inverse level order, call bubble_down.
### Complexity of heapify

- We call `bubble_down` \( \frac{n}{2} \) times
  - So \( O(n \log n) \)?
- But this is only an upper-bound
  - `bubble_down` is faster closer to the leaves
  - and most nodes live there!
  - we might be over-approximating the number of steps

### Efficient vs naive heapify

- For `naive_heapify` we found \( O(n \log n) \)
  - maybe we are also over-approximating?
- No: in the worst-case (sorted elements) we really need \( n \log n \) steps
  - try to compute the exact number of steps
- The difference:
  - `bubble_up` is faster closer to the root, but few nodes live there
  - `bubble_down` is faster closer to the leaves, and most nodes live there
- Note: in the average-case, the naive version is also \( O(n) \)

### Implementing ADTPriorityQueue

**Types**

```c
// An PriorityQueue is pointer to this struct
struct priority_queue {
    Vector vector;            // The data, in Vector for meta-class
    CompareFunc compare;      // The comparison function
    DestroyFunc destroy_value; // Function to destroy an element
};
```
ADTPriorityQueue implementation

Types.

// Ενα PriorityQueue είναι pointer σε αυτό το struct
struct priority_queue {
    Vector vector;  // Τα δεδομένα, σε Vector για μεταβλη
    CompareFunc compare;  // Η διάταξη
    DestroyFunc destroy_value;  // Συνάρτηση που καταστρέφει ένα στοι
};

Finding the max is trivial.

Pointer pqueue_max(PriorityQueue pqueue) {
    return node_value(pqueue, 1);  // root
}

For pqueue_insert, the non-trivial part is bubble_up.

// Αποκαθιστά την ιδιότητα του σωρού.
// Πριν: όλοι οι κόμβοι ικανοποιούν την ιδιότητα του σωρού, εκτός από
//       τον node που μπορεί να είναι _μεγαλύτερος_ από τον πατέρα το
// Μετά: όλοι οι κόμβοι ικανοποιούν την ιδιότητα του σωρού.
static void bubble_up(PriorityQueue pqueue, int node) {
    // Αν φτάσαμε στη ρίζα, σταματάμε
    if (node == 1)
        return;
    
    int parent = node / 2;  // Ο πατέρας του κόμβου. Τα node ids
    if (pqueue->compare(node_value(pqueue, parent), node_value(pqueue, node))
        node_swap(pqueue, parent, node);
    bubble_up(pqueue, parent);
}

// Πριν: όλοι οι κόμβοι ικανοποιούν την ιδιότητα του σωρού, εκτός από
// node που μπορεί να είναι _μικρότερος_ από κάποιο από τα παιδά
// Μετά: όλοι οι κόμβοι ικανοποιούν την ιδιότητα του σωρού.
static void bubble_down(PriorityQueue pqueue, int node) {
    // βρίσκουμε τα παιδά του κόμβου (αν δεν υπάρχουν σταματάμε)
    int left_child = 2 * node;
    int right_child = left_child + 1;
    int size = pqueue_size(pqueue);
    if (left_child > size)
        return;
    
    // βρίσκουμε το μέγιστο από τα 2 παιδά
    int max_child = left_child;
    if (right_child <= size && pqueue->compare(node_value(pqueue, left
        max_child = right_child;
    
    // Αν ο κόμβος είναι μικρότερος από το μέγιστο παιδά, swap και συνεχ
    if (pqueue->compare(node_value(pqueue, node), node_value(pqueue,
        node_swap(pqueue, node, max_child);
    bubble_down(pqueue, max_child);
}
### Other possible representations

<table>
<thead>
<tr>
<th>Operation</th>
<th>Heap</th>
<th>Sorted List</th>
<th>Unsorted Vector</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pqueue_create</code> (with data)</td>
<td>(O(n))</td>
<td>(O(n \log n))</td>
<td>(O(1))</td>
</tr>
<tr>
<td><code>pqueue_remove</code></td>
<td>(O(\log n))</td>
<td>(O(1))</td>
<td>(O(n))</td>
</tr>
<tr>
<td><code>pqueue_insert</code></td>
<td>(O(\log n))</td>
<td>(O(n))</td>
<td>(O(1))</td>
</tr>
</tbody>
</table>

All of them have some advantage
- Heaps provide a great compromise between insertions and removals

### Using ADTPriorityQueue for sorting

- We can easily sort data using ADTPriorityQueue
  - create a priority queue with the data
  - remove elements in sorted order
- When ADTPriorityQueue is implemented by a heap
  - this algorithm is called heapsort
  - and runs in time \(O(n \log n)\)

### Readings

Proofs of given statements can be found in the following book:
